Study Objectives: We investigated autonomic balance and resting metabolic rate to explore their possible involvement in obesity in hypocretin/orexin-deficient narcoleptic subjects.

Methods: Resting metabolic rate (using indirect calorimetry) and variability in heart rate and blood pressure were determined in the fasted resting state. Subjects included 15 untreated, hypocretin-deficient male narcoleptics and 15 male controls matched for age and body mass index.

Results: Spectral power analysis revealed greater heart rate and blood pressure variability in hypocretin-deficient male narcoleptic patients (heart rate: p = 0.01; systolic blood pressure: p = 0.02; diastolic: p < 0.01). The low to high frequency ratio of heart rate power did not differ between groups (p = 0.48), nor did resting metabolic rate (controls: 1767 ± 226 kcal/24 h; patients: 1766 ± 227 kcal/24h; p = 0.99).

Conclusions: Resting metabolic rate was not reduced in hypocretin-deficient narcoleptic men and therefore does not explain obesity in this group. Whether the increased heart rate and blood pressure variability—suggesting reduced sympathetic tone—is involved in this regard remains to be elucidated.

Keywords: narcolepsy, hypocretin, orexin, obesity, metabolism, heart rate variability, autonomic balance

Citation: Fronczek R; Overeem S; Reijntjes R; Lammers GJ; van Dijk JG; Pijl H. Increased heart rate variability but normal resting metabolic rate in hypocretin/orexin-deficient human narcolepsy. J Clin Sleep Med 2008;4(3):248-254.

Narcolepsy is a sleep disorder that affects 25-50 out of 100,000 people in Western countries. It is classically characterized by the tetrad of excessive daytime sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucinations. Obesity in narcolepsy was first described as early as the 1930s and has since been described repeatedly. The discovery of hypocretin/orexin deficiency in human narcolepsy with cataplexy and the fact that hypocretin peptides may be involved in metabolic control sparked renewed interest in the pathophysiology of obesity in narcolepsy. Indeed, various observations suggest that hypocretin deficiency is involved in the pathogenesis of weight gain in narcoleptic patients. Increased bodyweight has been reported in human narcolepsy as well as in the ataxin-3 hypocretin-deficient animal model of the disease. Moreover, patients with idiopathic hypersomnia, similarly marked by excessive daytime sleepiness but exhibiting normal cerebospinal hypocretin levels, are not obese.

There is evidence that hypocretin peptides stimulate feeding behavior: Injection of hypocretins into the lateral cerebral ventricle promotes food intake in rats, whereas ablation of hypocretin neurons leads to hypophagia in mice. Accordingly, narcoleptic humans and mice eat less than age and sex matched controls, which clearly indicates that other components of energy balance must drive weight gain in this disease. The effects of hypocretin peptides on wakefulness and the sympathetic nervous system may be involved. Injection of hypocretins into the lateral ventricle stimulates arousal and sympathetic activity in rats, elevating arterial blood pressure (BP), heart rate (HR), oxygen consumption, body temperature and plasma catecholamine levels. Thus, hypocretin deficiency could promote obesity through the concerted effects of several behavioral and neuroendocrine corollaries. It may reduce sympathetic tone and thereby resting metabolic rate. Moreover, since adipose tissue is innervated by both sympathetic and parasympathetic nerves, where sympathetic inputs stimulate lipolysis and parasympathetic signals are anabolic, dominance of parasympathetic tone could promote fat storage through direct effects on adipocytes. Finally, excessive daytime sleepiness may limit physical activity, which obviously would reduce daily energy expenditure. Thus, hypocretin deficiency may dampen sympathetic tone in narcoleptic patients, and thereby reduce resting metabolic rate and promote adipocyte lipogenesis to induce weight gain in the face of diminished food intake.

We studied resting metabolic rate and HR and BP variability, as a proximate measure of autonomic balance, in hypocretin-
deficient narcoleptic patients and healthy controls matched for
gender, body weight, and age. Since (lean) body mass is an
important determinant of resting metabolic rate, matching for
body weight was necessary to preclude confounding the data on
metabolic rate by anthropometric features of our volunteers. We
hypothesized that sympathetic tone and resting metabolic rate
per unit of (lean) body mass would be reduced in narcoleptic
subjects.

**MATERIALS AND METHODS**

**Subjects**

The study was approved by the local medical ethical
committee. All narcoleptic patients were male and fulfilled the
ICSD-2 criteria of narcolepsy with cataplexy. Patient
characteristics are shown in Table 1. Known reasons for obesity
other than narcolepsy formed an exclusion criterion. No pa-
tient used any medication at the time of the study. Four pa-
tients had received narcolepsy medication in the past, but at
least 2 years previous to the study. One patient had used meth-
lyphenidate until 2 weeks before participating. Hypocretin-1
was not detectable in the cerebrospinal fluid of any patient,
using a radioimmunoassay (Phoenix Pharmaceuticals, Inc.,
Belmont, CA) in duplicate 100 µL aliquots. All samples were
run in a single assay with a detection limit of 50 pg/mL and an
intra-assay variability less than 5%. We used a validated refer-
cence sample to adjust levels to previously reported values.

Healthy male controls were recruited using an advertisement
in a local newspaper.

**Metabolic Measurements**

Metabolic studies were conducted in 15 patients and 15 con-
trols. Subjects were instructed to fast and drink only water from
22:00 the night before until after the metabolic measurement
had been performed. Studies started at 09:00, when subjects
were asked to lie down in supine position for 30 minutes. Care
was taken to keep subjects awake during this period by talking
to them. Resting metabolic rate (RMR) was measured by indirect
calorimetry using a computerized open-circuit ventilated
hood system (Oxycon B; Jaeger, Breda, The Netherlands).
Measurements from the first 10 min of recording were not used
in the analysis as this period reflects the subjects coming to rest
and getting acquainted with the experimental conditions.

Oxygen consumption (VO₂, L/min) and carbon dioxide pro-
duction (VCO₂, L/min) were used to calculate the respiratory
index (VCO₂/VO₂). RMR and carbohydrate (C) and fat (F)
combustion were calculated using the Weir formula and were ex-
pressed as kilocalories per 24 h (per kilogram body weight) and
grams per minute (per kilogram body weight) respectively.

The following formulas were used:

\[
RMR (\text{kcal/24h}) = (3.9 \times VO_2) + (1.1 \times VCO_2) \times 1.44
\]
\[
C (\text{g/min}) = (4.55 \times VCO_2) - (3.21 \times VO_2)
\]
\[
F (\text{g/min}) = (1.67 \times VO_2) - (1.67 \times VCO_2)
\]

**Autonomic Measurements**

Autonomic measurements were recorded simultaneously
with the metabolic measurements. These measurements were
added to the original protocol and were obtained in 9 patients
and 9 controls, i.e., a subpopulation of the subjects included
for the metabolic measurements. HR was calculated from the
ECG. Beat-to-beat arterial BP was noninvasively measured
(Finometer, TNO-Biomedical Instruments, The Netherlands).
The hand used for these finger BP measurements was held in a
constant position at heart level. Analysis of autonomic data was
restricted to the last 20 min of the recording time, as was done
for metabolic measurements.

HR and BP calculations were performed using software
written in MatLab (MatLab v7.0, Mathworks, MA, USA). HR
variability (HRV) was estimated by calculating the mean and
SD of consecutive R-R intervals and with spectral analysis

N.D. Not Detectable; Current medication was stopped at least 2 weeks before participating in the current study. ? unknown
performed by interpolating the series of RR intervals by cubic splines, resampling the signal at 3 Hz and performing a fast Fourier transformation using a Hamming window.\textsuperscript{33} Power was calculated for the very low frequency (VLF, 0-0.04 Hz), low frequency (LF, 0.04-0.15 Hz), and high frequency (HF, 0.15-0.4 Hz) bands. Total power was calculated by adding the VLF, LF, and HF power values. The LF/HF ratio was also calculated.

Of note, the LF band is usually considered to represent sympa-thetically mediated baroreflex activity, while the HF band, largely derived from respiratory influences, mostly concerns parasympathetic activity. Increases in total power can be caused by a reduction in sympathetic tone.\textsuperscript{34,35} Although the LF/HF ratio is generally used as a measure of the autonomic parasympathetic-sympathetic balance,\textsuperscript{36} some authors regard it as an indication of sympathetic activity.\textsuperscript{37}

Mean systolic (SBP) and diastolic (DBP) BPs were calculated, and the total power in their frequency spectrum (calculated in a similar fashion as the HRV spectrum) was taken as an estimate of variability. Note that finger BP measurement using the aforementioned Finometer has a tendency to underestimate BP. While this can be corrected using additional conventional measurements,\textsuperscript{38} we chose not to do so because analyses involved groupwise comparisons.

**Statistics**

Differences between groups were calculated using Student’s \textit{t}-test for unpaired samples. Pearson correlation coefficient was used to evaluate potential correlations. P-values below 0.05 were considered significant.
Total power did not significantly correlate with age, age of disease onset or disease duration in patients (all $r < 0.64$, $p > 0.09$). HRV parameters did not differ between patients who had vs. those who had not received medication in the past ($p = 0.43$).

**DISCUSSION**

The pathogenesis of obesity in narcoleptic patients remains unexplained. Obviously, eating more or moving less are potential explanations. However, hypocretin neuron-ablated narcoleptic mice and human patients eat less than normal controls (total daily food intake, narcoleptic humans: $8,756 \pm 2,312$ kilojoules; controls: $10,640 \pm 3,129$ kJ; $p < 0.001$, data from Lammers et al.), which is in accordance with the orexigenic qualities of hypocretin peptides. Actigraphy studies have shown that, although periods of activity and inactivity are more scattered in narcoleptic subjects versus controls, the total intensity of physical activity does not differ.

Furthermore, narcoleptic subjects are more obese than equally active subjects suffering from idiopathic hypersomnia. Thus, hypocretin deficiency must have other metabolic consequences to explain why narcoleptic animals and humans are obese. Since hypocretin peptides were shown to activate the sympathetic nervous system and increase oxygen consumption in rats, we hypothesized that hypocretin deficiency would lead to a reduction of sympathetic tone and resting metabolic rate in patients with narcolepsy.

Spectral analysis of HR and BP variability revealed higher power in all frequency bands in narcoleptic patients, while the LF/HF ratio did not differ from that in healthy controls. These findings support our hypothesis that sympathetic tone is reduced in narcoleptic patients. However, at least one observation...
is heavily involved in autonomic control and that hypocretins stimulate sympathetic activity.\textsuperscript{45} Indeed, obese hypocretin neuron-ablated mice have lower sympathetic vasoconstrictor outflow.\textsuperscript{46} Alternatively, narcoleptic subjects may not have been as awake as the control subjects, although special care was taken to keep patients alert during the measurements. Narcolepsy is commonly seen as a loss of state boundary control, which means that patients are unable to remain awake steadily.\textsuperscript{42} A tendency to drift into drowsiness could lead to a higher variability in autonomic parameters, as autonomic control differs in the various sleep stages. The transition between wakefulness and sleep affects the power in both the HF and the LF band.\textsuperscript{43} Frequent shifts from waking to drowsiness might therefore cause increased HRV. Drowsiness would not only affect autonomic parameters, but might also have led to an underestimation of the RMR in narcoleptic subjects, since RMR is lower during sleep.\textsuperscript{44} However, this would mean that the actual RMR in narcoleptic subjects is higher, which obviously would not explain their obesity. We suggest that further studies should take drowsiness into account.

Hypocretin deficiency may directly inhibit sympathetic activity. Various studies have shown that the hypocretin system requires further clarification. The HF peak almost exclusively reflects vagal effects on HR. Thus, diminution of sympathetic tone cannot be the proximate cause of the increase of HF power we observed. However, studies employing selective antagonists of (para)sympathetic neurotransmitters revealed that reduction of sympathetic tone elevates both LF and HF power,\textsuperscript{34,35} perhaps because diminished sympathetic control causes larger than normal fluctuations in BP that in turn require considerable adaptive fluctuations of parasympathetic activity to control heart rate in response. Thus, reduced sympathetic tone can explain the high power in all frequency bands as well as the similarly elevated HF power in narcoleptic patients. Furthermore, sympathetic tone is already low in the supine position, so any further decreases are not likely to affect the ratio much under these circumstances,\textsuperscript{34,35} hampering a straightforward interpretation of this ratio.\textsuperscript{37} The only finding that is not readily compatible with decreased sympathetic tone is that mean HR was not lower in the narcolepsy group.\textsuperscript{34,35}

Values in the table are means ± standard deviation. T-tests were used to assess group differences. BMI, body mass index; HRV, heart rate variability; s, seconds; Hz, hertz, VLF, very low frequency; LF, low frequency; HF, high frequency; BMP, beats per minute; SBP, systolic blood pressure; DBP, diastolic blood pressure.
Surprisingly, although sympathetic activity drives resting energy expenditure, at least in rodents, RMR was similar in narcoleptic patients and controls. This may also hold for hypocretin-knockout mice, also having a normal RMR (C.M. Sinton, personal communication). Some caution is necessary, inasmuch as large numbers of subjects are required to detect small differences in energy expenditure with indirect calorimetry. Nonetheless, small differences in RMR can be relevant, as they may lead to weight gain in the long term. There is direct autonomic innervation of adipose tissue, implying that a low sympathetic tone can directly promote fat accrual.

Other studies on autonomic nervous function in narcoleptic patients reported no abnormalities during provocations and no primary disturbances between 18:00 and 20:00 or during sleep. An increased LF/HF ratio compared with controls was found just before sleep onset, but this was thought to be related to the impairment of the sleep-wake cycle in narcolepsy and not to a primary disturbance. The sample of 9 patients used for autonomic measurements in our study was relatively small, increasing the chance of type II errors. We thus advocate replicating and extending the studies on autonomic activity in narcoleptic patients.

In a recent study, RMR was determined in 7 typical narcolepsy patients with cataplexy who were assumed to be hypocretin-deficient. The control group consisted of 9 healthy controls. RMR tended to be lower in narcoleptic patients (p = 0.07). Note that the controls were not matched for BMI in that study. In our larger patient and BMI-matched control sample, metabolic parameters were so similar between the two groups that increasing the number of subjects is not likely to result in a significant difference in RMR. To obtain a definite answer, a large, collaborative study in subjects with a broad range of BMIs should be conducted. It would also be of interest to include leptin measurements in such a study. Given the controversy in the literature, multiple measurement points over the day should then be performed.

In conclusion, resting metabolic rate appears to be normal in narcoleptic humans as determined by indirect calorimetry. However, there are signs of reduced sympathetic activity, which may lead to fat accrual through direct effects on adipocytes.
